## A Hitchhikers Guide to the Black Arts (of Earth system modelling)

Vb: 'How low can you go?'

Stuff to keep in mind:

"There are known knowns. These are things we know that we know. There are known unknowns. That is to say, there are things that we know we don't know. But there are also unknown unknowns. There are things we don't know we don't know."

Donald Rumsfeld, former US Secretary of Defense

## 13. The last glacial

13.1 You will be using the same reduced resolution idealized 'modern' configuration of *c*GENIE as in (12), but it is rather more idealized than you have seen for the modern Earth (although not quite as idealized as for the snowball Earth experiments). It also differs in that in addition to having a carbon cycle (which was omitted from the majority of your previous session) it includes a representation of deep-sea sediments and interaction between the preservation and burial of CaCO<sub>3</sub> and ocean chemistry. For an over-view of the sediment model and what time-scales and nature of carbon cycle interaction between ocean and sediment you can expect – read: *Ridgwell and Zeebe* [2005] (over-view of the role that calcium carbonate production by life and deep-sea sediment play in the global carbon cycle) and *Ridgwell and Hargreaves* [2007].

Note that you will be using a new *c*GENIE configuration, so before you forget ... make cleanall ... You will also be using a different 'run genie' script: runcgenie.t48.sh when running the model (it configures different (faster) time-stepping).

13.2 Take the new model for a spin by running on from the *re-start*: exp0\_glacial\_SPINUP. This is a steady-state climate+carbon cycle experiment that includes the deposition of CaCO<sub>3</sub> in deep-sea sediments and the balance between weathering (solute input to the ocean) and burial (output). Try running ('briefly', but 100 years would not be too tedious for this faster configuration!):

./runcgenie.t48.sh cgenie\_eb\_go\_gs\_ac\_bg\_sg\_rg.p0000e.BASESFe.t48
LABS exp13\_glacialALT\_CONTROL 100 exp0\_glacialALT\_SPINUP

Note that the *base-config* (cgenie\_eb\_go\_gs\_ac\_bg\_sg\_rg.p0000b.BASESFe.t48) is different from before (and specifies the use of a sediment model 'sg' in GENIE for instance). It also includes an iron cycle alongside phosphate as a limiting nutrient (the 'Fe' bit) and takes fewer time steps per year ('t48'). In fact, you'll notice that is it rather faster than previous configurations :)

The degraded resolution (and fewer time-steps per year) is important in being able to run *c*GENIE on sediment time-scales (see *Ridgwell and Hargreaves* [2007]) within a reasonable time-scale (i.e., the time available to you for carrying out some glacial  $CO_2$  research using the model). Unfortunately, that the resolution is rather more degraded than previously means that you will need to be aware of additional limitations and caveats associated with this configuration than previously (these limitations and caveats are left for <u>you</u> to identify and take on board).

The user-config is set up as a 'control' in that it continues on from the re-start without making any adjustments to the climate or biogeochemsitry (compared to the re-start) but will show up any residual drift in the spin-up. Note that the user-config has been set up so that the global carbon cycle is 'open' - that is to say, that there is an input of carbon (and alkalinity) to the ocean from weathering, and a loss due to preservation and burial of CaCO<sub>3</sub> in deep-sea sediments. Depending on the state of ocean chemistry (and biology) and weathering, these two fluxes (input and output) do not have to balance, and hence ocean carbonate chemistry can change with time. The spin-up may not have the two fluxes (input and output) perfectly balanced, hence a 'control' experiment will reveal any residual drift. A residual drift can be dealt with if it is relatively small and near linear and you have a control, because any experiment you carry out will likely also incorporate (or be biased) by the same residual drift, hence running a *control* gives you something to directly contrast with your experiment minus the control (e.g., a difference map or simple subtraction of global numbers) will give you the effect of whatever parameters you changed in the experiment and corrected for any drift. (Note that in previous Labs we were a bit lazy, and difference maps were often created with respect to year 1 of an experiment - strictly, they should have been created relative to the same year of a parallel control experiment, i.e., results at year 100 should have been contrasted with the year 100 results of the control.) Depending on exactly how you design your experiments in investigating glacial CO<sub>2</sub>; a single control experiment might suffice.

There is a new set of outputs from this configuration of *c*GENIE, including sediment output (from the 'SEDGEM' module). For instance, the composition of the sediments at the <u>very end</u> of a model experiment (hence unlike BIOGEM, which saves a series of time-slices) is saved by the SEDGEM module in the sedgem subdirectory of your results directory in a netCDF file called fields\_sedgem\_2d.nc. (Note that there is some duplication of results saving, because a series of

time-slices of sediment composition are also saved in the 2D biogem netCDF file fields\_biogem\_2d.nc alongside with sea-ice extent etc.).

For instance, the 2D distribution of wt%  $CaCO_3$  – which is the weight fraction of calcium carbonate (CaCO<sub>3</sub>) in the surface sediments of the deep ocean (i.e., how much plankton carbonate shell material is there compared to other stuff in the mud at the bottom of the ocean?) is saved under a variable called: sed\_CaCO3. How much carbonate material there is tells you both something about how many carbonate shell secreting plankton were living at the ocean surface above and what is the chemistry of the deep ocean like that these tiny shells were preserved and did not dissolve. To gauge to what degree the faster configuration of GENIE might provide an adequate representation of the interaction between ocean chemistry and sediment composition (e.g., in CaCO<sub>3</sub> buffering of CO<sub>2</sub> release and 'carbonate compensation'), the output should be contrasted to observational-based maps as well as (higher resolution) model results (e.g., as presented by *Ridgwell and Hargreaves* [2007]). Appreciate that *c*GENIE does not reproduce reality ... particularly at this lower resolution, but does it get the broad patterns right (is it more right than wrong, or more wrong than right)? Do you think the model-data misfits might be important? (Note that there is a reconstruction of the glacial pattern of CaCO<sub>3</sub> in sediments that is available and may be of use in constraining your glacial CO<sub>2</sub> hypothesis, or at least testing it against data.)

- 13.1 Before embarking upon some glacial experiments (below) other model outputs/fields you might also keep in mind and for which some data/observational constraints on your glacial CO<sub>2</sub> 'solution' may be available (e.g. see *Kohfeld and Ridgwell* [2009] and refer to this for the full references of papers cited below), include:
  - The 2D fields\_biogem\_2d.nc field: phys\_seaice ('sea-ice cover'), for which some glacial sea-ice limit information exists. (CLIMAP)
  - The 2D fields\_biogem\_2d.nc field: ocn\_sur\_temp ('surface-water temp') (or view the surface ocean layer in the 3D file), for which 2 (one older, one newer) comprehensive datasets exists it would be reasonable to question whether you achieve an adequate glacial (surface) climate state and if not, whether this impacts any bias (and in which direction) to your CO<sub>2</sub> solution. (CLIMAP, MARGO)
  - The 2D fields\_biogem\_2d.nc field: sed\_CaCO3 ('sediment core-top CaCO3') (also available from the sedgem model output), for which some glacial CaCO<sub>3</sub> distribution data/estimates exist. (Old Catubig paper in GBC)
  - The 2D fields\_biogem\_2d.nc field: phys\_opsia ('Atlantic streamfunction'). While poorly resolved in this model configuration, many (glacial) model studies report the circulation field and hence they provide a point of comparison for your GENIE-based research.
  - The 2D fields\_biogem\_2d.nc field: ocn\_D\_DIC\_13C (' planktic-benthic difference DIC\_13C') and also the individual planktic (surface) and benthic (bottom) fields. A significant amount of  $\delta^{13}$ C data exists in the literature for both glacial and interglacial states.
  - The 2D fields\_biogem\_2d.nc field: ocn\_ben\_02 (' bottom-water O2') (and also horizontal slices in the 3D file). Ideally, no-where in the ocean should anoxia (no oxygen) occur. It certainly should not be widespread across one or more ocean basins if your glacial CO<sub>2</sub> solution is to get published in Nature ;)
  - The 2D fields\_biogem\_2d.nc field: ocn\_ben\_sal ('bottom-water sal') (and also in the 3D file as horizontal slices), for which some estimates exists for a few places in the ocean. (Jess Atkins Science paper)
  - The 2D fields for surface and deep PO<sub>4</sub> (and also in the 3D file as horizontal slices) as some proxy evidence exists for changes in nutrient utilization. (Cd/Ca proxies – e.g. papers by Elderfield and Rickaby)

Also refer to the 3D netCDF files and the time-series where helpful.

Note here that the spin-up provided is 'modern' and hence glacial data cannot be directly contrasted – the above suggestions/guidance are intended as a starting point only.

- 13.2 In your glacial CO<sub>2</sub> investigations, 2 separate initial modifications of the model will nudge it in the vague direction of a glacial state (e.g., see *Kohfeld and Ridgwell* [2009]):
  - A modification of surface (actually 'planetary') albedo to try and take account of some of the cooling influences of the large (Northern Hemisphere) ice sheets that were present during the last glacial but which are not calculated or explicitly taken into account in the version of *c*GENIE you are using.
  - A modification of greenhouse gas radiative forcing (as per in the snowball Earth experiments) to take into account the lower CO<sub>2</sub>, CH<sub>4</sub>, and N<sub>2</sub>O concentrations in the atmosphere during the last glacial. While you will be attempting to reproduce ~190 ppm atmospheric CO<sub>2</sub> (and hence deduce the reasons for low glacial CO<sub>2</sub>), you may not necessarily achieve this, and you have no means of explicitly controlling the other greenhouse gases, so you may as well get the radiative forcing and hence the glacial climate state as close as possible before trying to adjust the carbon cycle. But it is up to you whether you prefer to not 'cheat' and have whatever CO<sub>2</sub> cGENIE simulates, directly affect climate (and hence feed back on CO<sub>2</sub>).

The glacial boundary conditions are implemented as follows:

To achieve a pseudo-glacial planetary albedo modification, add the following lines to a user-config file (un un-comment the lines in the user-config expl2\_glacial):
 # adjusted planetary albedo

```
# adjusted planetaly all
ea_albedop_offs=0.200
ea_albedop_amp=0.360
ea_albedop_skew=0.0
ea_albedop_skewp=4
ea_albedop_mod2=-15.000
ea_albedop_mod4=-2.500
ea_albedop_mod6=0.000
```

Note that *c*GENIE, as configured here, does not have a land surface scheme (no snow cover), nor clouds, so a planetary albedo is prescribed (see Figure). This varies with latitude and is parameterized after a fully coupled GCM simulation. There is a parameter which controls how the albedo varies as a function of latitude, which can be adjusted:  $ea_albedop_amp=0.360$ 

There is also a parameter that sets the baseline (minimum) albedo: <code>ea\_albedop\_offs=0.200</code>

Albedo is primarily a sum of the baseline value plus the Equator-to-pole slope (times the latitude). The other parameters control lesser, harmonic modulations of this basic profile.

• For glacial radiative forcing, add the lines:

```
# glacial CO2 radiative forcing
ea_radfor_scl_co2=0.6835
# glacial CH4 radiative forcing
ea_radfor_scl_ch4=0.5
# glacial N2O radiative forcing
ea_radfor_scl_n2o=0.8
```

If you like – you can carry out separate experiments to test the effect of each of these in turn and hence to learn the effect and impact on atmospheric  $CO_2$  of each individually before combining them. Ideally, these lines should ultimately be included in all (glacial) experiments that you require glacial albedo and radiative forcing for.

By all means play around with the albedo and radiative forcing climate boundary conditions, although one might wonder the reasoning behind adjusting radiative forcing below e.g. that appropriate for full glacial conditions. However, the planetary albedo is less certain as implemented in the model. For instance, one might legitimately adjust this to achieve appropriate last glacial sea surface temperatures (SST), or rather: a glacial-interglacial difference in SSTs that is similar between model and data.

13.3 By this point, you should have created a new (mostly) spun-up model state, incorporating: (i) higher planetary albedo, and (ii) lower greenhouse gas forcing. The duration of this new, glacial spin-up needs to be sufficient to bring the system into (a new) equilibrium (of which the slowest adjusting component will be sediment composition (wt% CaCO<sub>3</sub>), although continuing changes in wt% CaCO<sub>3</sub> will to some extent be reflected in continuing changes in *p*CO<sub>2</sub> (why?)).

Before carrying on, check that everything is 'correct' (or at least: understandable) so-far. In particular: confirm that you have a colder ocean (due to altered albedo **and/or** greenhouse radiation forcing) ... no, seriously! You never know what might have gone wrong with a simple slip of the keyboard ... Surface ocean temperature also has established proxies for its glacial value and so the model can be contrasted against data.

The file biogem\_series\_ocn\_temp.res is the time-series results file for ocean temperature – the 2nd column is the mean ocean temperature, the 3rd column is mean sea surface temperature (SST), and the 4th mean benthic (deep (> 2 km) ocean floor). How much colder has it become? Is this realistic? Analyze the SST distribution (the surface field of the 3D netCDF time-slice file, or the 'sur\_\*' variables in the 2D netCDF file) – how does this compare to observations? In the book chapter the data-based difference in SST between the LGM and Holocene is given. However, the map given is for the (glacial-interglacial) difference, which happily is something you have previously learned to do using Panoply (I hope!).

Also, what is the  $CO_2$  impact of lower SSTs? Note that you may not be able to directly compare your  $CO_2$  prediction with all previous studies (e.g. summarized in the book chapter) because in your model, sea-ice and ocean circulation will also have been affected to some extent by the climate change. (How much have they been affected? There are also some proxies for sea-ice extent as well as ideas and hypotheses about ocean circulation changes.) Many (but not all) previous model studies have simply estimated  $CO_2$  changes due to temperature change with fixed sea-ice and circulation fixed, by prescribing a different ocean surface temperature for the  $CO_2$ solubility calculation. (This is a little beyond the scope of what you are expected to do here, but can be done in GENIE.)

13.4 Unless you are \*extremely\* lucky and already have a value of atmospheric CO<sub>2</sub> that is 90 ppm lower than pre-industrial (~278 ppm) ... (WTF?!) – you may want to test other changes that might have taken place between glacials and interglacials that affected CO<sub>2</sub>. Obviously a spot of creating of new *user-config* files will be in order here (perhaps using: expl2\_glacial as a template, but it is entirely up to you). Ideally, you would test the impact of each change <u>individually</u> first before combining them, so as to develop a better understanding of the different ways in which CO<sub>2</sub> is controlled (and the associated impacts on other elements of the global carbon cycle and climate) <u>before</u> bunging everything in together.

Before diving straight in – note the number of different modifications of the global carbon cycle that might be considered and tested in the model. What is your methodological strategy going to be? Are you going to add all of the modifications into a single run and hope that you can understand what has happened at the end? (I hope not!) Are you going to run all the modifications individually (how?). Are you going to try combinations to test whether any combine non-linearly? You will want to make use of the cluster queue and submit at least some of the experiments. You will also need to already have a good idea of how long to run them before (hopefully you obtained this knowledge from the idealized perturbation experiments in **Lab VI**).

Some <u>suggestions</u> (i.e., this not an exhaustive list, nor a prescribed one and not everything necessarily has to be done!):

• **Global weathering rate**. Refer to *Ridgwell and Zeebe* [2005] for the role of weathering. Also to *Kohfeld and Ridgwell* [2009] for some references to the changes in weathering that might have taken place between glacial and interglacial. The namelist parameter that controls the annual rate of solute input into the ocean is: rg\_par\_weather\_CaC03=0.9E+13

Either edit this value (under heading: # --- WEATHERING ---) or add a new line at the end of the *user config* file specifying the value you want. Units are mol of CaCO<sub>3</sub> weathered per year.

This parameter could also be adjusted to implicitly simulate the effect of a change in carbonate deposition in coral reefs and other shallow water carbonates, changes that GENIE cannot simulate explicitly. See *Ridgwell et al.* [2003]

(http://www.seao2.org/pubs/ridgwell\_et\_al\_2003a.pdf) for references and discussion of the sort of change in carbonate deposition on the shelves that might have taken place. A decrease in CaCO<sub>3</sub> removal on the continental shelves can be simulated by increasing the weathering flux to the open ocean. In other words, you can look at the parameter rg\_par\_weather\_CaCO3 as representing the residual weathering flux to the open ocean, after some of the weathering flux has been removed in coastal areas. Even if global weathering of the continents did not change, any reduction in CaCO<sub>3</sub> precipitation and removal on the continental shelves would result in an increased solute flux to the open ocean.

[**HINT**: keeping track of how mean sediment wt% CaCO<sub>3</sub> changes will be helpful, as may 2D sediment distributions and ultimately, the sediment core records.]

• **Iron fertilization**. Read up on this first, e.g., see references in *Kohfeld and Ridgwell* [2009]. The glacial was dustier than present, hence there can only have been increased aeolian iron supply to the ocean surface. However, what is not so clear is how important (relative to Fe being upwelled) aeolian Fe is today, let alone during the last glacial ...

Anyway: one way to increase the aeolian Fe supply to the ocean surface is simply to increase the solubility of the Fe in dust. This is controlled by the parameter: bg\_par\_det\_Fe\_sol=0.0015

with the default being a global average dust Fe solubility of 0.15% (fraction == 0.0015).

Increasing it will increase the Fe input to the ocean surface everywhere (in direct proportion to the modern spatial pattern). The pattern of total aeolian Fe supply is recorded in the (2D BIOGEM) variable: misc\_sur\_fFetot\_mol, with the dissolved component under: misc\_sur\_fFe\_mol (misc\_sur\_Fe\_sol is the map of solubility, which in GENIE is not uniform in space – any idea what the reason for this assumption might be?).

(A glacially-explicit map of dust deposition could also be applied in place of the modern deposition map – if you would like to test this, I can create one, but note that there are very significant 'errors' in re-gridding dust maps to this highly simplified continental topography.) [**HINT**: viewing maps of particulate organic carbon (POC) export may be particularly helpful.]

• **Remineralization depth**. There is no temperature control on the rate of bacterial degradation of sinking organic matter (see: book chapter + references therein) but the effect of lower ocean temperatures and a slower rate of bacterial degradation of organic matter can be simulated by specifying that particulate organic matter reaches greater depth before being remineralized (and CO<sub>2</sub> and PO<sub>4</sub> released back to the seawater). The parameter that controls the e-folding depth reached by particulate organic matter before remineralization is:

bg\_par\_bio\_remin\_POC\_eL1=589.9451

Either edit this value (under heading: # --- REMINERALIZATION ---) or add a new line at the end of the *user config* file specifying the value you want. Units are m. Read *Ridgwell et al.* [2007] for additional discussion of this parameter. See Figure 2-4 in *Ridgwell* [2001] (http://www.seao2.org/pubs/ridgwell\_thesis.pdf) for an illustration of how the flux of particulate organic matter decreases with depth in the ocean, plus references therein.

There is also an associated parameter:  $bg_par_bio_remin_POC_frac2$ , which sets a fraction of organic matter that is assumed to settling through the water column completely un-altered (currently assigned a value of 0.025 == 2.5%), but this is arguably less appropriate to change than the remineralization length-scale of the more labile fraction (97.5% of exported particulate organic carbon).

[**HINT**: viewing distributions of PO<sub>4</sub> and/or O<sub>2</sub> in the ocean may be helpful. Perhaps also  $\delta^{13}$ C.]

• **Macro nutrient inventory and uptake**. Suggestions have been made that nutrients were used more efficiently during the LGM, meaning that for the same nutrient uptake at the surface more carbon was exported to depth in the ocean. See: *Omta et al.* [2006]. There are also a bunch of (relatively old) hypotheses concerning differences between glacial and modern ocean in how much nitrate (NO<sub>3</sub><sup>-</sup>) there was. There is no NO<sub>3</sub><sup>-</sup> in this version of GENIE (just PO<sub>4</sub><sup>3-</sup> and Fe), but an analogous change can be made to the phosphorous cycle.

For the nutrient-to-carbon ratio in organic matter, the relevant parameter is: bg\_par\_bio\_red\_POP\_POC=106.0

To change the default value (106.0), add a new line at the end of the *user-config* file specifying the value you want. A larger number means that  $PO_4$  is being utilized more efficiently and more organic matter ir being produced for the same nutrient consumption. If you would like to test the effect of adding more  $PO_4$  to the (glacial) ocean, add:  $bg_ocn_dinit_8=1.0E-6$ 

which will add 1  $\mu$ mol kg<sup>-1</sup> of PO4 uniformly to the ocean. (A larger/smaller number will obviously increase the glacial nutrient inventory by more/less.) Note that adjusting the ocean PO<sub>4</sub> inventory should only be done <u>once</u> (and not accidentally in each successive experiment!).

You'll be seeing similar parameters to this later, so it is just worth mentioned in passing what it is for: it is so that you can adjust the inventory (concentration) of any tracer in the ocean compared to a *re-start*. Otherwise, the only ways to adjust the ocean inventory are to start from scratch ('cold', no *re-start*) with a different initial value, or create a *forcing* of the ocean. This single parameter is much simpler, but only changes things uniformly throughout the ocean. Units are mol kg<sup>-1</sup> (except for temperature and salinity).

[**HINT**: in evaluating the consequences of Redfield ratio and nutrient inventory change, viewing distributions of  $PO_4$  and/or  $O_2$  in the ocean may be helpful. Also ocean sediment CaCO<sub>3</sub> distributions.]

CaCO3:POC rain ratio. Kicked off by a classic 1994 Nature paper by Archer and Maier-Reimer (see: *Kohfeld and Ridgwell* [2009]), one powerful means of changing atmospheric CO<sub>2</sub> that has been proposed involves changes in the export ratio between CaCO<sub>3</sub> (shells) and POC (particulate organic matter). Such a change in ratio could come about through a variety of ways (e.g., via the 'silica leakage hypothesis' (see: *Kohfeld and Ridgwell* [2009]) and also through the direct effect of Fe on diatom physiology (see *Watson et al.* [2000] in Nature and also Supplemental Information). There are also ideas about an opposite ocean acidification effect, whereby the less acidic glacial (compared to modern) ocean led to increased calcification and CaCO<sub>3</sub> export. Note that this response (higher saturation == great calcification) is encoded into your model configuration – see *Ridgwell et al.* [2007b]. In GENIE, the CaCO<sub>3</sub>:POC rain ratio is controlled (technically: scaled) by the parameter: bg\_par\_bio\_red\_POC\_CaCO3=0.03

The pattern of CaCO<sub>3</sub>:POC rain ratio is not uniform across the ocean (why? (see: *Ridgwell et al.* [2007, 2009]), and its pattern can be viewed in the (2D BIOGEM) netCDF variable: misc\_sur\_rCaCO3toPOC.

[HINT: viewing sediment CaCO<sub>3</sub> distribution may be helpful.]

- **Sea-ice extent**. Changes to sea-ice extent have already taken place due to changes in radiative forcing and planetary albedo (made previously). There is no much you can do to further adjust sea-ice extent, other than via further changes to climate (via radiative forcing and/or albedo).
- Atlantic circulation. There are a variety of ideas and hypotheses about glacial ocean circulation and what influence it had on atmospheric CO<sub>2</sub>. At least with respect to making tests and experiments in models, a common ploy has been to produce a collapsed AMOC (e.g., see *Chikamoto et al.* [2008] (*JGR* 113)). Rather than apply a continuous freshwater forcing to the ocean throughout an extended (sediment interaction) time-scale (why would this not be a good idea?), there is a parameter in the model which creates an adjustment of the salt balance between the different ocean basins (to make the Atlantic more salty

compared to the Pacific). (In other words: salt/freshwater is re-partitioned between the ocean basins rather than 'new' freshwater or salt externally added.) This parameter is: ea\_28=0.726862013339996340

Setting it to e.g., 0.0, will result in a collapsed AMOC. But maybe that is too extreme? (You might read up a little on the glacial ocean circulation literature and chose a value that gives as an appropriate change to Atlantic circulation as you can judge from the data and literature.)

[**HINT**: viewing distributions of PO<sub>4</sub> and/or O<sub>2</sub> and/or  $\delta^{13}$ C in the ocean may be helpful. Also ocean sediment CaCO<sub>3</sub> distributions.]

• **Global ocean circulation / 'brine rejection'**. Some recent research has focussed on the possible role of 'brine rejection' in creating a saltier Antarctic bottom waters (e.g. see Adkins et al. 2002 Science paper) and hence a denser and more stratified deep ocean,, with the idea being this will trap carbon more efficiently. For a very recent study (and references therein), see:

http://www.clim-past.net/6/575/2010/cp-6-575-2010.html

GENIE has the capability to include this effect (at least crudely) and similarly to *Bouttes et al.* [2010]. For this, three namelist parameter values need to be set:

bg\_ctrl\_force\_GOLDSTEInTS=.TRUE. bg\_par\_misc\_brinerejection\_frac=0.1 bg\_par\_misc\_brinerejection\_jmax=9

The first, simply allows the BIOGEM biogeochem module to directly influence ocean circulation. The second is the fraction of salt, rejected during sea-ice formation (e.g., see *Bouttes et al.* [2010]) that is transferred directly to the bottom-most (underlying) ocean cell in the model. The first sets a latitude limit (counted in cells) to the effect – a value of 9 will restrict brine rejection to the Southern Ocean; a value of 18 will allow it to take place in the North Atlantic as well. (Note that in e.g., *Bouttes et al.* [2010], the effect is considered only in the Southern Ocean.)

[**HINT**: viewing distributions of PO<sub>4</sub> and/or O<sub>2</sub> and/or  $\delta^{13}$ C in the ocean may be helpful. Also ocean sediment CaCO<sub>3</sub> distributions.]

- **MISC**. There are of course other possibilities for adjusting the model, although you need an a priori reason for doing so and what about the possible glacial state of global carbon cycling and climate you are trying to encapsulate. Examples might include wind speed (or air-sea gas exchange).
- 13.5 Even if you achieve atmospheric CO<sub>2</sub> of ca. 190 ppm (and actually, with some mechanisms on their own and also in combination, it is quite easy to achieve this), how do you know if you are 'right'? Many of the important constraints are summarized in *Kohfeld and Ridgwell* [2009] and *Archer et al.* [2000]. In particular:
  - The distribution of the CaCO<sub>3</sub> content of deep-sea sediments. e.g., see Figure 6 in Archer et al. [2000]. You are not 'allowed' to blanket the entire ocean floor with CaCO<sub>3</sub> if you want to be consistent with the paleoceanographic record of the LGM ;)
     The predicted distribution of the CaCO<sub>3</sub> can be used to assess your circulation change note that there is much less CaCO<sub>3</sub> in sediments in the North Atlantic at the glacial [*Archer et al.*, 2000]. See: *Chikamoto et al.* [2008] for a model assessment of the impact of AMOC changes on deep-sea sediment composition.
  - The ocean should not go 'anoxic' (i.e., little to no dissolved oxygen left) over large expanses. (But you might consider this relative to the modern configuration i.e., should the modern simulation under-estimate oxygen concentrations in the deep ocean, so will the glacial simulation, even if you get the mechanisms exactly 'right'.)
  - There is a map of estimated changes in the biological flux to the ocean floor in *Kohfeld and Ridgwell* [2009] (also read the original reference). In the 2D netCDF file, the variable focnsed\_POC gives you the flux of particulate organic matter (actually, carbon) to the ocean floor. By constructing a difference map of your glacial-interglacial predicted changes, you could contrast directly to the *Kohfeld et al.* [2005] reconstruction.

- The GENIE model is set up to predict δ<sup>13</sup>C distributions. See: *Curry and Oppo* [2005]. There is also an atmospheric record of δ<sup>13</sup>C (also predicted by GENIE) – see: *Smith et al.* [1999] and a more recent paper in GBC: *Lourantou et al.* [2010] ('Constraint of the CO<sub>2</sub> rise by new atmospheric carbon isotopic measurements during the last deglaciation ').
- Other proxies offer varying constraints at the global or regional scales. e.g., see: *Elderfield and Rickaby* [2000] (Cd/Ca ratios).

Note that commonly in (glacial  $CO_2$ ) modeling studies, a steady state (or quasi steady state) simulation is run for the glacial (and compared to pre-indsutrial). The version of *c*GENIE you have is sufficiently fast to do this quite effectively. It is possible to do non-state (glacial-interglacial) simulations, e.g. *Ridgwell* [2001], but this is rather more involved.

Also note that in all of the above possible adjustments to the global carbon cycle, the mechanism of carbonate compensation is operating. Hence there will be direct (changes in carbon cycling within the water column) and indirect (interaction between ocean and deep-sea sediments) processes operating that will affect  $CO_2$ . Carbonate compensation will typically take a few 10s of thousands of years to fully adjust atmospheric  $CO_2$ . Not all previous modeling studies include this effect and in some cases it can drastically influence the predicted change in atmospheric  $CO_2$ .

- 13.6 Finally ... maybe you have achieved close to 190 ppm and are not unreasonably consistent with various paleoceanographic proxies and are hence feeling rather pleased with yourself ... O sorry I forget to mention a little something:
  - There is as approximately ~3% (~1 PSU) increase in salinity (and other dissolved tracers) due to the presence of large (Northern Hemisphere) ice sheets, and hence loss of freshwater from the ocean and lower sea-level associated with the last glacial.

Ahhhh ... and I also forgot:

• It is thought that there was a release of carbon stored on land in vegetation and soils during glacial climates. (*c*GENIE has some capabilities to model changes in terrestrial carbon storage and hence predict this, but you are not using a version with this science module enabled.)

Unfortunately – both these effects act to increase atmospheric  $pCO_2$  at the last glacial (or decrease it across the deglacial transition, which ever way around you like to think of it). So you are actually rather further off achieving a net 90 ppm difference than you thought.

To test the effect of a ~3% increase in salinity at the last glacial, you need to add the line:  $bg_ocn_dinit_{2=1.0}$ 

## which will increase salinity by 1 PSU.

For the reduction in terrestrial carbon storage, you need to try a further experiment (on top of and/or following on from the salinity change experiment). The parameter will be: bg\_ocn\_dinit\_3

However, relating this, because it is in units of  $\mu$ mol kg<sup>-1</sup> (mean ocean concentration change) of DIC, to a more manageable number (PgC or GtC as per literature) takes a little thought. If you e.g. open the file: biogem\_year\_49999\_500\_diag\_GLOBAL\_AVERAGE.res from the glacial *spin-up*, you see a bunch of summary (mostly) ocean information from this experiment, including: Ocean DIC ..... : 2300.027 umol kg-1 <-> 0.2659944E+19 mol

which gives you the relationship between concentration and total mol. (You could also have looked in the ocean DIC time-series file.) If 2300.027  $\mu$ mol kg<sup>-1</sup> as an ocean average corresponds to 0.2659944×10<sup>19</sup> mol, then 2.300027×10<sup>-3</sup> mol kg<sup>-1</sup> (the units of the parameter) is 0.2659944×10<sup>19</sup> mol = 3.1919×10<sup>19</sup> g carbon = 3.1919×10<sup>4</sup> PgC = 31919 PgC.

So 1 PgC will be equivalent to a change in mean ocean DIC of:

 $2.300027 \times 10^{-3}$  /  $3.1919 \times 10^{4} = 7.2058 \times 10^{-8}$ . Obviously, you can scale up to e.g. 500 PgC from here. (Remember: that if you want to add carbon to the ocean as if it had come from the terrestrial biosphere at the time of the last glacial, the value of bg\_ocn\_dinit\_3 is positive.)

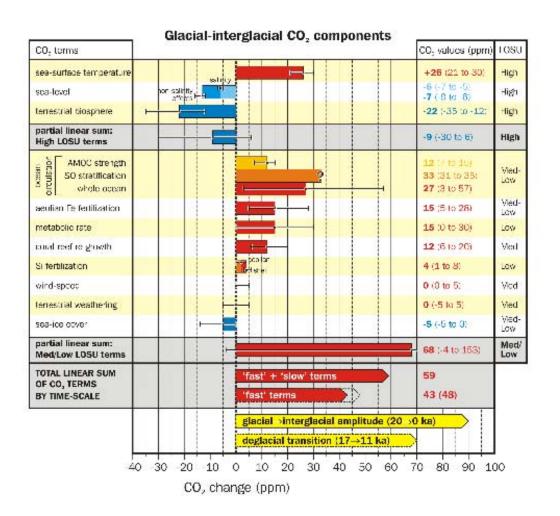

Note that while the magnitude of the glacial-interglacial salinity and sea-level change is well constrained, that of the terrestrial biosphere is not (e.g., see: *Kohfeld and Ridgwell* [2009]). In

investigating the potential causes of low glacial  $CO_2$ , do not feel constrained to necessarily run with 500 PgC ... (Think for yourselves!)

These two adjustments are effectively one-off changes imposed on the global climate and carbon cycle. By adjusting salinity, you add 1 PSU of salinity to the entire ocean and obviously you only want to do this <u>once</u>, not multiple times (other wise you will get an increasingly salty ocean ...). Similarly with the terrestrial carbon change.

You may want to start by checking that ocean salinity should end higher than the preindustrial *restart* that was originally provided (or compared to your best guess glacial run). The file  $biogem\_series\_ocn\_sal.res$  is the time-series results file for ocean salinity – the 2nd column is the mean ocean salinity. Originally it was 34.904 PSU (or ‰), now it should be about 35.9. Note how atmospheric  $pCO_2$  has responded to the change in ocean volume and sea-level (and tracer concentrations) alone. How does this reduced resolution version of *c*GENIE compare to published estimates (too much; too little; why? or if 'about right' – does this mean that you can completely trust *c*GENIE from now on?).

Also check that that the amount of carbon you intended has been changed. You can calculate the total ocean + atmosphere carbon inventory from the atmospheric  $CO_2$  time-series file (biogem\_series\_atm\_pCO2.res - column #2 is the global  $CO_2$  inventory in mol) and the ocean total dissolved carbon time-series file (biogem\_series\_ocn\_DIC.res - column #2 is the global DIC (total dissolved inorganic carbon) inventory in mol). Note you will have to convert from mol to gC (or PgC) in order to compare to the amount you requested. Also note that the ocean+atmosphere inventory slowly changes in response to your DIC adjustment. If you are summing both everything in the ocean plus everything in the atmosphere (and there is no explicit terrestrial biosphere in this version of *c*GENE) – where is it going / coming from ... ? (Hint: refer to the mechanisms discussed in the lecture (and papers) relating deep-sea sediments and weathering to changes in total carbon (e.g., fossil fuel  $CO_2$  release.)
